Abstract

1A532

Augmented Fourier polynomials, in which constant and linear terms have been added to an ordinary Fourier series, appear to offer a means for representing the vertical profile of the horizontal wind speed. Reasons for selecting this function, and methods of its computation and application, are given. Polynomial coefficients are presented for mean monthly winds over Cape Canaveral, Florida, and for four consecutive soundings over Montgomery, Alabama.

## Mathematical Wind Profiles<sup>1</sup>

Arnold Court, Robert R. Read,<sup>2</sup> and Gerald E. Abrahms

Office of the Chief Scientist  
Lockheed-California Co.  
Burbank, Calif.

### 1. Introduction

Mathematical representation of the vertical profile of wind is desirable for many purposes, and essential for the rigorous comparison of profiles and the prediction of profiles by statistical regression techniques. Because wind is a two-dimensional vector (neglecting the vertical component, which is at least an order of magnitude smaller than the horizontal components), the vertical profile of the instantaneous wind is a curve in three-dimensional space. The graphical and analytical difficulties in describing such a curve have thus far prevented any systematic description of complete wind profiles. In this report, various possible methods of representation are explored, and one of them, using complex Fourier series, is developed in detail. Application of the method, and its evaluation, will be the subjects of future reports.

---

1. Prepared under Contract NAS-8-5380 with Aero-astrodynamics Laboratory, George C. Marshall Space Flight Center, N.A.S.A.

2. Professor of Mathematics, U. S. Navy Postgraduate School, Monterey, and consultant to the Lockheed-California Co.

Notation has been chosen carefully for consistency and clarity.

The wind speed toward the East is denoted by  $x$ , that toward the North by  $y$ . Their vector resultant is called  $\underline{s}$ , and the modulus or absolute value of this resultant is  $s$ :

$$(1.1) \quad |\underline{s}|^2 = s^2 = x^2 + y^2.$$

The direction of this resultant, in degrees clockwise from North, is

$$\theta = \text{arc sin } x/s = \text{arc cos } y/s.$$

This double definition eliminates the ambiguity of sign inherent in a definition based on  $\text{arc tan } y/x$ . The meteorological convention for angles, used also in surveying and navigation, differs from the mathematical practice, in which angles are measured counterclockwise from the  $x$ -axis (East in meteorological practice). For the mathematical development, therefore, the direction is designated as

$\phi$

$$(1.2) \quad \phi = \frac{3}{2}\pi - \theta = \text{arc sin } y/s = \text{arc cos } x/s,$$

and hence measured counterclockwise from East.

Alternative to the cartesian  $(x,y)$ , polar  $(s,\theta)$ , and vector  $(\underline{s})$  representations of a wind vector is its representation as a complex variable,  $\zeta$ :

$$(1.4) \quad \zeta = \underline{s} = x + iy = se^{i\phi}.$$

To reduce the number of subscripts, a second wind vector will be denoted as  $(u,v)$ ,  $(u,\psi)$ ,  $\underline{v}$ , or  $\gamma = w \exp(i\xi)$ . Height upward from the ground will be designated as  $h$ , atmospheric density as  $\rho$ , true correlation as  $\rho$  and its sample estimate as  $r$ , true variance as  $\sigma^2$  and its sample estimate as  $s^2$ , and gravity as  $g$ .

The complex conjugate of a complex number will be denoted by an asterisk:

$$(1, \zeta) \quad \zeta^* = x - iy = ze^{-i\phi}$$

Therefore the real and imaginary parts of the complex number  $\zeta$  are

$$\text{script } \begin{cases} R(\zeta) = (\zeta + \zeta^*)/2 = (e^{i\phi} + e^{-i\phi})/2 = \cos \phi = x, \\ i L(\zeta) = (\zeta - \zeta^*)/2 = (e^{i\phi} - e^{-i\phi})/2 = i \sin \phi = iy. \end{cases} \begin{matrix} \nearrow R \\ \searrow L \end{matrix} (1,6)$$

Other notation will be identified when used.

## 2. Representations

Because a wind profile is a curve in three-dimensional space, its graphical representation on two-dimensional paper requires elimination of one dimension. Various graphical methods have been used for many years, each with some advantages and many disadvantages. The four basic methods, illustrated in Fig. 1 with mean January winds for Cape Canaveral, Florida, are:

- a. Each component, separately, vs. height;
- ~~b.~~ b. Speed and direction, separately, vs. height;
- c. Velocity hodograph.
- d. Position hodograph.

The first two methods require mental addition of values from the two lines to give a picture of the actual wind vector, and its changes. This difficulty is eliminated in the hodographs, in which the vertical dimension (or time) is indicated only by successive points along the path.

A hodograph is a curve connecting the end-points of successive vectors, drawn from a common origin. The vectors may be successive in height, to represent the wind profile, or in time, to show the time variation of wind. The former application is used here, but the mathematical formulation is equally applicable to the time series case. The vectors may represent the actual wind velocity at each level, or they may represent the integral of the velocity, which gives the position of an object, such as a balloon, rising with constant speed through the wind field. The usual plotting-board representation of a pilot balloon trajectory is a position hodograph of the vertical wind profile, while the similar trajectory of a constant-level balloon is a ~~position~~ prepared hodograph of the time variation of wind. A position hodograph can be ~~prepared~~ from wind velocity information by plotting the successive vectors additively rather than from a common origin.

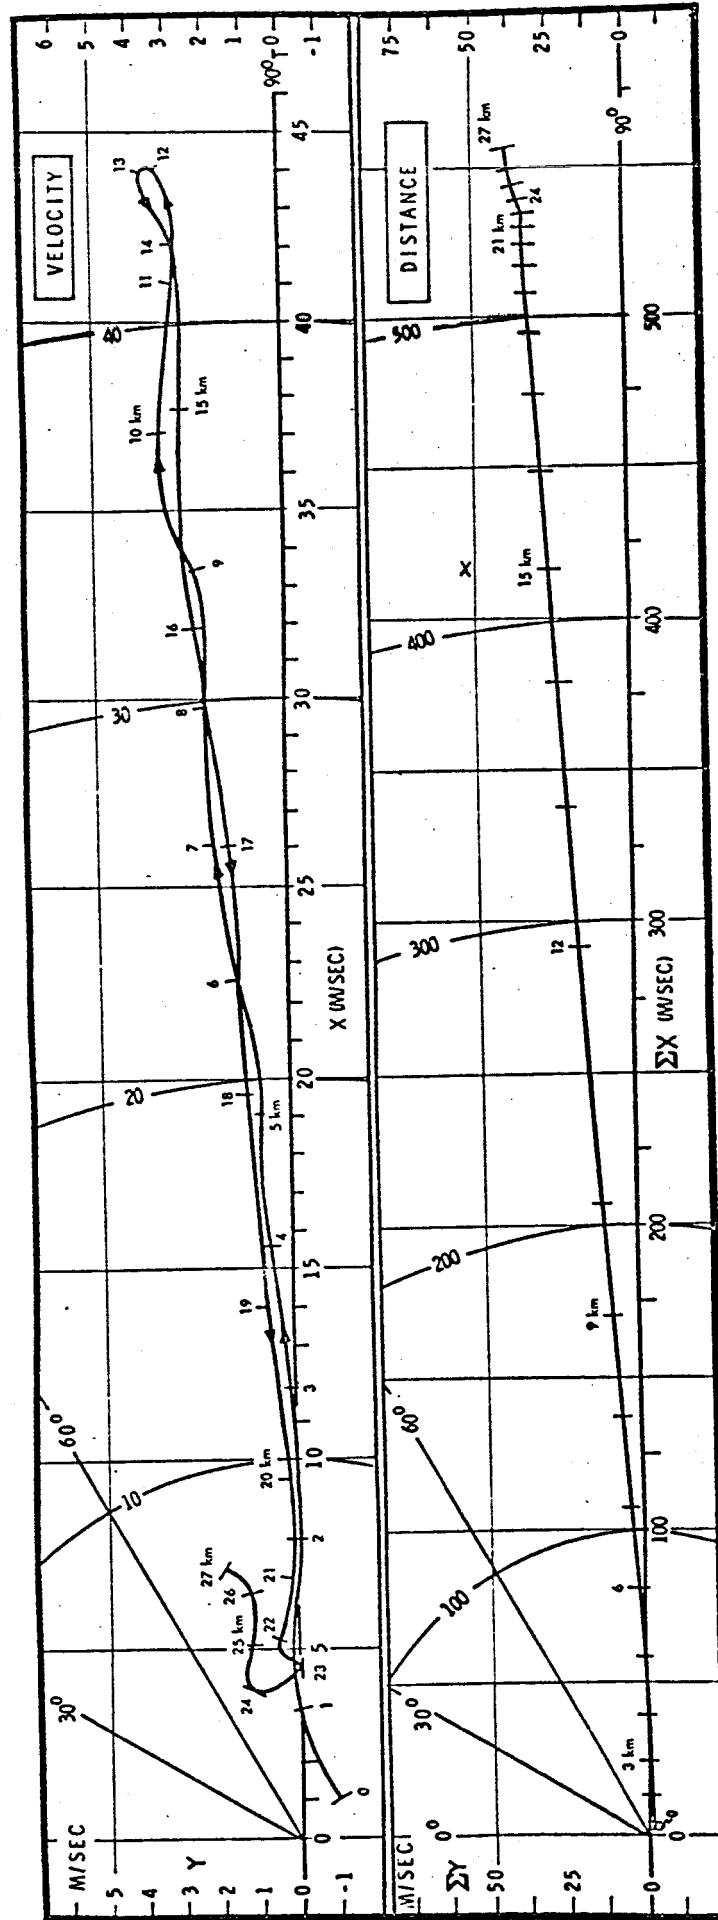

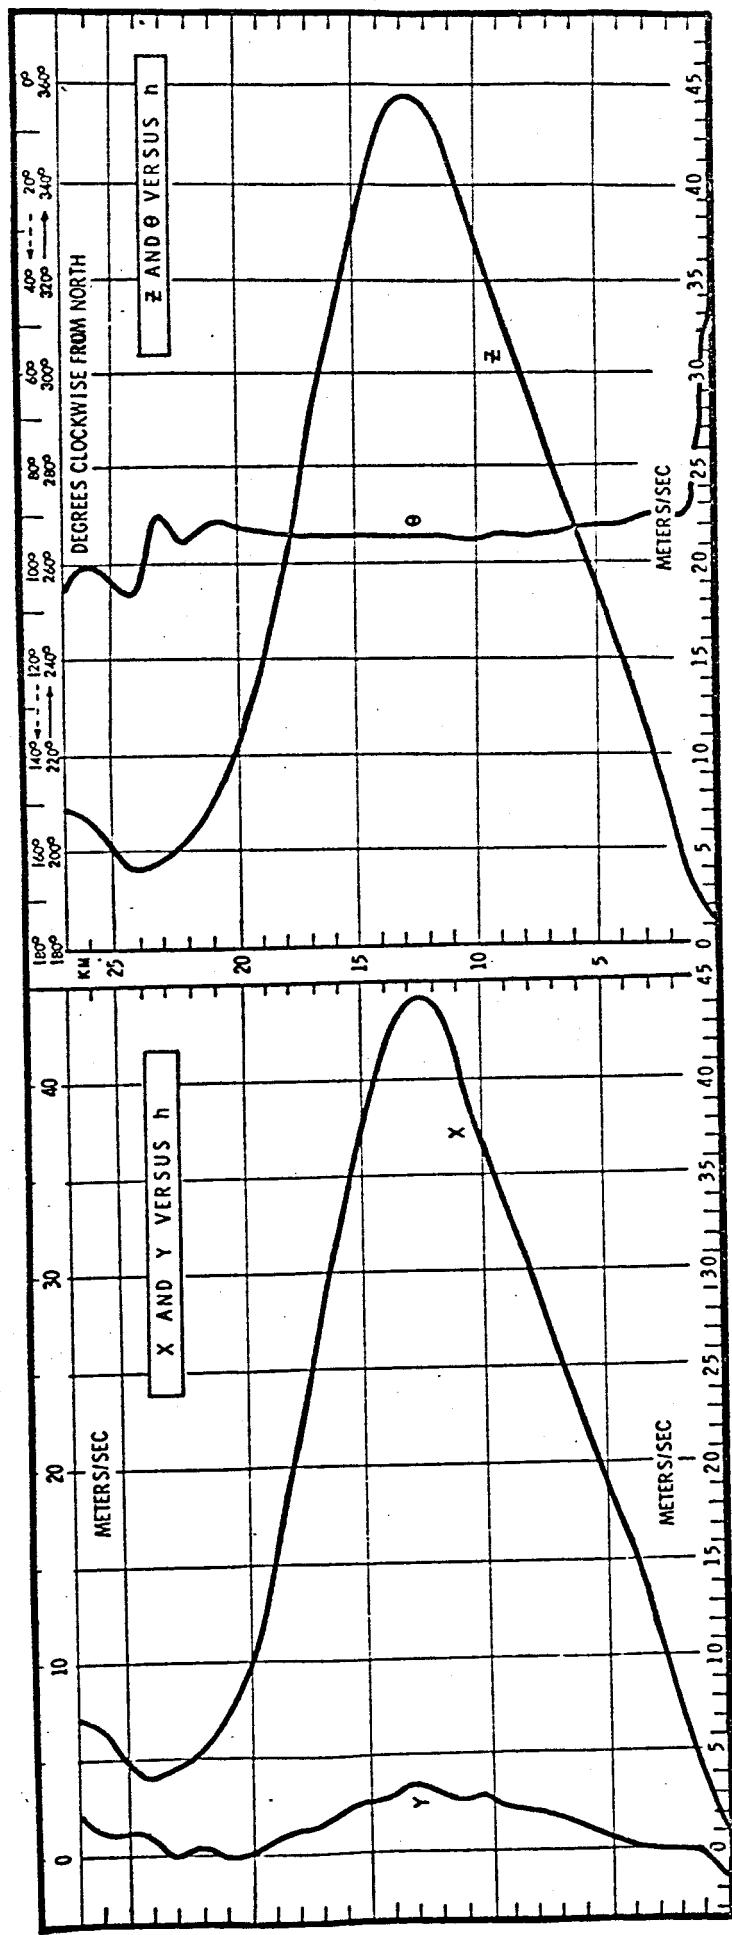

Fig. 1.

Hodographs appear more suitable for mathematical representation of the vertical wind profile than separate representations by components, or by speed and direction. But choice between the two hodographs, velocity and position, is more difficult. Fortunately, the computational procedures of fitting a function to observations are the same for either type of hodograph, since the purpose is merely to obtain an analytic function describing the curve.

When positions actually are measured (as in most meteorological observations using balloons, rising or falling), the position hodograph should be fitted. One differentiation of the fitted function then will give the velocity hodograph function, and a second differentiation the wind shear, which is of considerable importance. Actually, most routine wind information is obtained from finite differences of balloon positions, and shears from finite differences of these computed velocities, i.e. by smoothed second differences of the basic observations.

When wind velocities are obtained directly, as by sound ranging, the velocity hodograph should be fitted. One differentiation then will yield shears, while integration gives the positions to which they apply. Such positional information is needed for studies of the trajectories of falling or suspended objects, such as radioactive fallout or toxic pollutants.

Any mathematical function used to approximate a hodograph must be continuous and have continuous first and second derivatives. Since the hodograph is a vector-valued function  $\underline{z}(h)$  of a scalar argument,  $h$ , in practice representation by components is more convenient. Compactness of representation and relative ease of manipulation make the complex form,

$$x(h) + i y(h) , \quad z(h) \exp [i \phi(h)] ,$$

suitcd for an attempt at developing an expression for  $\underline{z}(h)$ .

### 3. Functions

Selection of a mathematical function to approximate the vertical wind profile, as represented by its position or velocity hodograph, must be based largely on convenience and general suitability, including possession of continuous derivatives. Meteorological and hydrodynamic theory are as yet inadequate to provide a definitive functional form, except for certain height ranges.

In the lowermost 10 meters of the atmosphere, air flow increases without height without material change in direction (Hess, 1959). When the temperature lapse rate is neutral, the logarithmic wind profile appears to fit available observations:

$$\text{tau} \quad (3.1) \quad z = (\sqrt{\tau/q} / k) \ln (h/h_0),$$

where  $\tau$  is the eddy stress,  $q$  the density,  $k$  von Karman's constant, and  $h_0$  a "roughness parameter." When the lapse rate is not neutral, an exponential profile seems more appropriate:

$$(3.2) \quad z = z_1 (h/h_1)^m,$$

where  $z_1$  is the wind speed at height  $h_1$  (usually a few centimeters) and  $m$  is a positive exponent less than unity. A generalization, for variable lapse rates, is offered by the Deacon profile:

$$\text{beta} \quad (3.3) \quad z = [(\sqrt{\tau/q} / k(1-\beta))] [(h/h_0)^{1-\beta} - 1]$$

For several hundred meters above this boundary layer, wind increases in speed with height, and turns clockwise, in the northern hemisphere, generally according to the Ekman spiral. At about the 10 meter level, the

wind is directed toward the left of the geostrophic wind, which blows along the isobars at 1 km or higher. The wind vector at height  $h$  in this spiral or friction layer is

$$(3.4) \quad z(h) = z_g \left[ e^{i\phi} - e^{-ch} e^{i(ah - \phi)} \right].$$

Here  $z_g$  is the magnitude of the geostrophic wind, blowing at an angle  $\phi$  (in mathematical notation) to the positive x-axis, and  $a$  is a function of density, coriolis force, and eddy viscosity. Actual winds do follow this Ekman spiral when the upper wind flow is straight or only slightly curved, and the lowermost kilometer of air has not appreciable horizontal gradients of temperature.

Above the spiral layer, wind speed generally increases with height up to the level of maximum wind, which usually occurs slightly below the tropopause at 10 to 12 km. Often the increase in speed with height is at about the same rate as the decrease of density with height, so that between 5 and 10 km <sup>Eggen's</sup> "law" states that the momentum is constant. A justification of this empirical rule, deduced from cloud and pilot balloon observations 70 years ago by Clayton in Massachusetts and Eggen in France, was offered by Humphreys (1929, pp. 135-136).

Above the maximum wind layer, wind speed decreases with height to a minimum, on the average, at 22 to 25 km, but no law or rule describing this decrease, or the accompanying change in direction, has yet appeared. Thus, while some theoretical formulations are available for wind behavior in the boundary and spiral layers, few guidelines can be found for the form of a function to describe the wind profile above 1 km.

#### 4. Series

In the absence of any theory on which to base a functional form for wind profile description, some empirical function must be chosen. Logical candidates for this purpose are polynomials. The wind vector  $\underline{z} = (x, y)$  could be represented as a function of height,  $h$ , by two separate polynomials, one for each component:

$$(4.1) \quad x_{h,m} = \sum_{k=0}^m a_k h^k, \quad y_{h,n} = \sum_{k=0}^n b_k h^k$$

where  $m$  and  $n$  are the numbers of terms required for satisfactory fit or agreement of the polynomial with the observations. Agreement would be determined by the variance (mean squared difference) of the observations about the polynomials. The absolute or unconditional variances are, respectively,  $\sigma_x^2$  and  $\sigma_y^2$ , and the conditional variances  $\sigma_{x,m}^2$  and  $\sigma_{y,n}^2$ :

$$\begin{aligned} \sigma_x^2 &= \bar{v}^{-1} \sum (x_h - \bar{x})^2 = \bar{v}^{-1} \sum x_h^2 - (\bar{x})^2, \\ (4.2) \quad \sigma_{x,m}^2 &= \bar{v}^{-1} \sum (x_h - x_{h,m})^2 = \bar{v}^{-1} \sum x_h^2 - \bar{v}^{-1} \sum x_{h,m} (x_{h,m} - 2x_h) \end{aligned}$$

and similarly for  $\sigma_y^2$  and  $\sigma_{y,n}^2$ . (All summations are for  $h = 0, 1, 2, \dots, 2N$ , and  $\bar{v} = 2N + 1$ .) The extent to which the variance of  $x$  is reduced by use of an  $m$ -term polynomial is

$$(4.3) \quad \sigma_x^2 - \sigma_{x,m}^2 = \bar{v}^{-1} \sum x_{h,m} (x_{h,m} - 2x_h) - (\bar{x})^2.$$

Of greater interest than this absolute reduction in variance is the relative reduction, or squared correlation (sometimes called the coefficient of determination):

$$(4.4) \quad r_{x,m}^2 = \frac{\sigma_x^2 - \sigma_{x,m}^2}{\sigma_x^2} = \frac{\sum x_{h,m} (x_{h,m} - 2x_h) - \bar{v}(\bar{x})^2}{\sum x_h^2 - \bar{v}(\bar{x})^2}.$$

similar expressions yield the absolute and relative reductions in the variance of  $y$ .

As more and more polynomial terms are used, i.e. as  $m$  and  $n$  increase, the variance reduction increases and the correlations approach one, attaining this value for  $m = n = n$ . But when  $r^2 = .9$ , the fit of the polynomial to the observations is considered adequate for most purposes, although in some cases values as high as .95 are desired.

However, the various terms of the polynomials may not be equally effective in reducing the variance. A higher power, such as  $a_4 h^4$ , may be more effective than a lower one. Hence the terms should be chosen not in simple order, but according to the amount of variance reduction that they provide. A more efficient polynomial, in the sense of having fewer terms, would be formed from those terms, regardless of their exponents, providing the greatest reduction in variance, or highest correlation. The various terms,  $a_k h^k$ , should be arranged according to their contribution to the variance reduction. Coefficients ordered in this way may be denoted as  $a_{(k)}^{(k)}$ , and the first  $m$  of them will be considered to form the index set  $M$ . In this notation, the polynomial providing the required (e.g. 90%) ~~maximum~~ relative reduction in variance is

$$\epsilon \quad (4.5) \quad z_{h,M} \in \sum_{(k)=1}^n a_{(k)}^{(k)} h^k = \sum_{k \in M} a_k h^k,$$

and similarly for  $y_{h,M}$ .

Such polynomials would provide suitably efficient procedures for representing each of the components separately. But they offer no link between the components; they do not apply to the wind vector itself. When results obtained by two such polynomials are combined to provide estimates

of the wind vector at each level, excessive inter-level shears could be indicated. Hence they do not seem particularly suited for the mathematical representation of wind vectors.

The same objections apply to the fitting of a complex variable by a single power series with complex coefficients:

$$(4.4) \quad h_M = \sum_{k \in M} c_k h^k = \sum_{k \in M} (a_k + i b_k) h^k \\ = \sum_{k \in M} a_k h^k + i \sum_{k \in M} b_k h^k .$$

These objections to expressing the wind components as polynomial functions of height apply regardless of the method of estimating the polynomial coefficients. Orthogonal polynomials, while possessing the great advantage that they need not be recomputed after selection of the highest-order term contributing significantly to the variance reduction, are not better in these respects than simple power series.

## 5. Fourier

Complex trigonometric polynomials (Fourier series) are not subject to the same drawbacks as univariate polynomials, just discussed. The estimation of the coefficients of each component (i.e., the real and imaginary parts) is based on both components of the observed wind, and hence such a complex series actually estimates the vector, or entire complex number, rather than separate components.

Fourier series often are used to represent functions known to be periodic, but are not restricted to such use. Lighthill (1960) declares (p. 4) that a common application is "to represent a function which is not periodic, but instead is defined in the first place only in a restricted interval." Wind information usually is available only for a restricted interval, covering perhaps 30 km in the vertical. Description of the time and space variations in such a 30-km profile may be possible through the fitting of Fourier series or polynomials.

Such polynomials, however, have no linear terms. Since the wind often increases rather regularly with height, at least over certain height ranges, a linear term obviously is desirable in any expression for the vertical wind profile. This can be provided by defining a plane about which the actual wind observations vary, and then describing such variations by Fourier polynomials. The required plane is defined by two straight lines, in the vertical  $x-h$  and  $y-h$  planes, respectively, that represent the individual wind components.

At the original observations of the wind at level  $h$ ,

$$(5.1) \quad \zeta_h = x_h + i y_h = z_h \exp(i\phi),$$

may be expressed in terms of the least squares linear trends as

$\eta_{\text{eta}}$

(5.2)

$$\zeta_h = c_x + d_{00} h + \eta_h$$

The departure -

$\zeta_h = u_h + i v_h$  is given by

(5.3)

$$u_h = x_h - c_x - a_{00} h, \quad v_h = y_h - c_y - b_{00} h.$$

The linear coefficients (reasons for the double zero subscripts will be apparent later) are

$$(5.4) \left\{ \begin{array}{l} c_{00} = \frac{\sum x_h h - \sum \bar{x}_h \sum h}{\sum (h - \bar{h})^2}, \quad b_{00} = \frac{\sum y_h h - \sum \bar{y}_h \sum h}{\sum (h - \bar{h})^2}. \end{array} \right.$$

The constant terms are

(5.5)

$$c_x = \bar{x} - a_{00} \bar{h}, \quad c_y = \bar{y} - b_{00} \bar{h}.$$

Thus the variations of the wind vector about the least squares plane are

(5.6)

$$\eta_h = \zeta_h - (\bar{\zeta} - d_{00} \bar{h}) - d_{00} h,$$

where  $d_{00} = a_{00} + i b_{00}$  is obtained from (5.4).

Fourier polynomials describing  $\eta_h$  are

(5.7)

$$\eta_{h,M} = \sum_{j \in M} d_j \exp(i \lambda_j h), \quad \lambda = 2\pi/\nu.$$

The complex coefficients  $d_j = a_j + i b_j$  are estimated (as explained in Appendix A, and discussed in the next Section) from the  $\nu$  values of  $\eta_h$ , obtained from the  $\nu$  observations of  $\zeta_h$ . Summation is over the set  $M$  of the  $m$  terms contributing most to the reduction in variance, as discussed in the previous Section for univariate polynomials.

After the  $\{d_j\}$  have been estimated and the set  $H$  chosen, the resulting Fourier polynomial can be augmented by the constant and linear terms to provide a complete expression for the actual wind profile:

$$(5.8) \quad f_{h,H} = \bar{f} + d_{00} (h - \bar{h}) + \sum_{j \in H} d_j \exp(i \lambda_j h).$$

Application of this expression for the wind profile to actual wind observations is discussed in the following Sections.

## 6. Properties

Expansion of (5.7) shows that the estimation of each component of the wind vector  $\eta_{h,H}$  and hence of  $\zeta_{h,H}$  involves coefficients from both the real and imaginary parts of the polynomial:

$$(6.1) \quad \begin{aligned} \eta_{h,H} &= \sum_{j \in H} (a_j + i b_j) (\cos \lambda_j h + i \sin \lambda_j h) \\ &= \sum_{j \in H} (a_j \cos \lambda_j h - b_j \sin \lambda_j h) \\ &\quad + i \sum_{j \in H} (b_j \cos \lambda_j h + a_j \sin \lambda_j h). \end{aligned}$$

The least squares estimators of the complex coefficients  $d_j$  are, as shown in Appendix A,

$$(6.2) \quad \begin{aligned} d_j &= a_j + i b_j = \frac{1}{\sqrt{N}} \sum_{h=0}^{2H} \eta_h \exp(-i \lambda_j h) \\ &= \frac{1}{\sqrt{N}} \sum_{h=0}^{2H} (v_h + i y_h) (\cos \lambda_j h + i \sin \lambda_j h) \\ &= \frac{1}{\sqrt{N}} \sum_{h=0}^{2H} (v_h \cos \lambda_j h + y_h \sin \lambda_j h) \\ &\quad + i \frac{1}{\sqrt{N}} \sum_{h=0}^{2H} (v_h \cos \lambda_j h - y_h \sin \lambda_j h). \end{aligned}$$

That these estimators actually minimize the sum of the squared departures of the observations from the least-squares regression plane is shown in Appendix A. These ~~squared~~ squared departures are the sums of the squared departures of the two components; divided by  $N$ , the total number of observations, they yield the conditional variance about the polynomial:

$$(6.3) \quad \frac{1}{N} \sigma_{\eta_j H}^2 = s_{\eta_j H}^2 = \sum_{h=0}^{2H} s_{\eta_j H, H}^2 = \sum_{h=0}^{2H} (\eta_h - \eta_{h,H}) (\eta_h - \eta_{h,H})^*$$

A major purpose of this study is to determine the magnitude of the absolute reduction in variance,  $\sigma_{\eta_j}^2 - \sigma_{\eta_j H}^2$  and the relative reduction,  $r_{\eta_j H}^2$ .

when a wind profile, from which observations are obtained at equal height intervals, is approximated by (5.8) for  $n \leq 4$ . If the representation is adequate,  $\zeta_{h,M}$  may be evaluated for any value of  $h$ , not necessarily those equally-spaced values at which  $\zeta_h$  was observed. This would provide a continuous representation of a wind profile originally described for discrete points only. In addition, the function (5.8) can be differentiated to provide a continuous representation of the wind shear,  $\partial \zeta_{h,M} / \partial h$ . Alternatively, the  $\zeta_h$  may be the balloon positions at successive heights, and differentiation then will provide wind speeds at any height.

Not only do the coefficients  $\{d_j\}$ , estimated by (6.2), minimise  $S_{\zeta,M}^2$ , but, as discussed in Appendix B, they seem to be approximately orthogonal, although the precise extent of any slight dependence between them is still to be determined.

Orthogonality insures that for any set  $\{N\}$  of coefficients,  $S_{N,M}^2 = \sum S_{\zeta,j}^2$ , that is, that the contribution of each term to the total variance does not depend on what other terms are included in that total. This desirable property has been assured in the preliminary applications of Fourier polynomials to the description of wind profiles.

Orthogonality properties are increased when the original observations  $\zeta_h$ , expressed as departures  $\eta_h$  from the least-squares plane, have all the same variance. Thus, rather than  $\eta_h$  as defined by (5.6), computations of  $d_j$  by (6.2) should use  $\eta_h / \sigma_{\eta,h}$ , where  $\sigma_{\eta,h}^2$  is the variance  $\eta_h$ . Since  $\eta_h$  is, by (5.6), a linear function of  $\zeta_h$ , their variances are the same. Such variances should be used, when available, to adjust the values of  $\eta_h$ , as just indicated.

When the original observations  $\eta_h = x_h + i y_h$  are means, as for a month or season, variances are available for such adjustment. But when they are single observation, the proper choice of values is not obvious. In the following Sections, examples are given of profiles computed from mean values adjusted for variance, and of profiles fitted to individual sets of observations without variance adjustment. The propriety of this second procedure, although it seems to provide an adequate fit, requires further investigation.

Another topic for further study is the method of computing the plane about which the departures  $\eta_h$  are taken. The Fourier polynomials may provide an even better approximation to the observations if this trend plane is constructed through the mean point so that the first and last observations (lowest and highest wind observations) are equidistant from it.

## 7. Applications

Augmented Fourier polynomials, as developed in the preceding two Sections, were fitted to two sets of wind data to determine whether the method showed sufficient promise to warrant further study and development. Results of such application, presented in this Section, are quite encouraging.

One set of wind data was composed of monthly mean winds, at 1-km levels, over Cape Canaveral, Florida (now Cape Kennedy). They are based on 5 years of observations (the first 321 days were at nearby Patrick Air Force Base), 1956-1961. Missing observations had been interpolated before averaging, so that sample sizes were the same at all levels. These data were furnished by Mr. Orvel E. Smith of the Aero-astrodynamics Laboratory, George C. Marshall Space Flight Center, in advance of publication.

The other set was made up of four consecutive observations, at 6-hour intervals, over Montgomery, Alabama, on 9 January 1956. These were the first four consecutive soundings, each reaching to at least 25 km, in an extensive compilation of winter and summer soundings furnished by the National Weather Records Center, U. S. Weather Bureau, at Mr. Smith's request. These soundings also contained data on atmospheric density, so that momentum density as well as wind speed could be fitted by augmented Fourier polynomials. (Units of momentum density, the product of wind speed and atmospheric density, are dynes per square centimeter.)

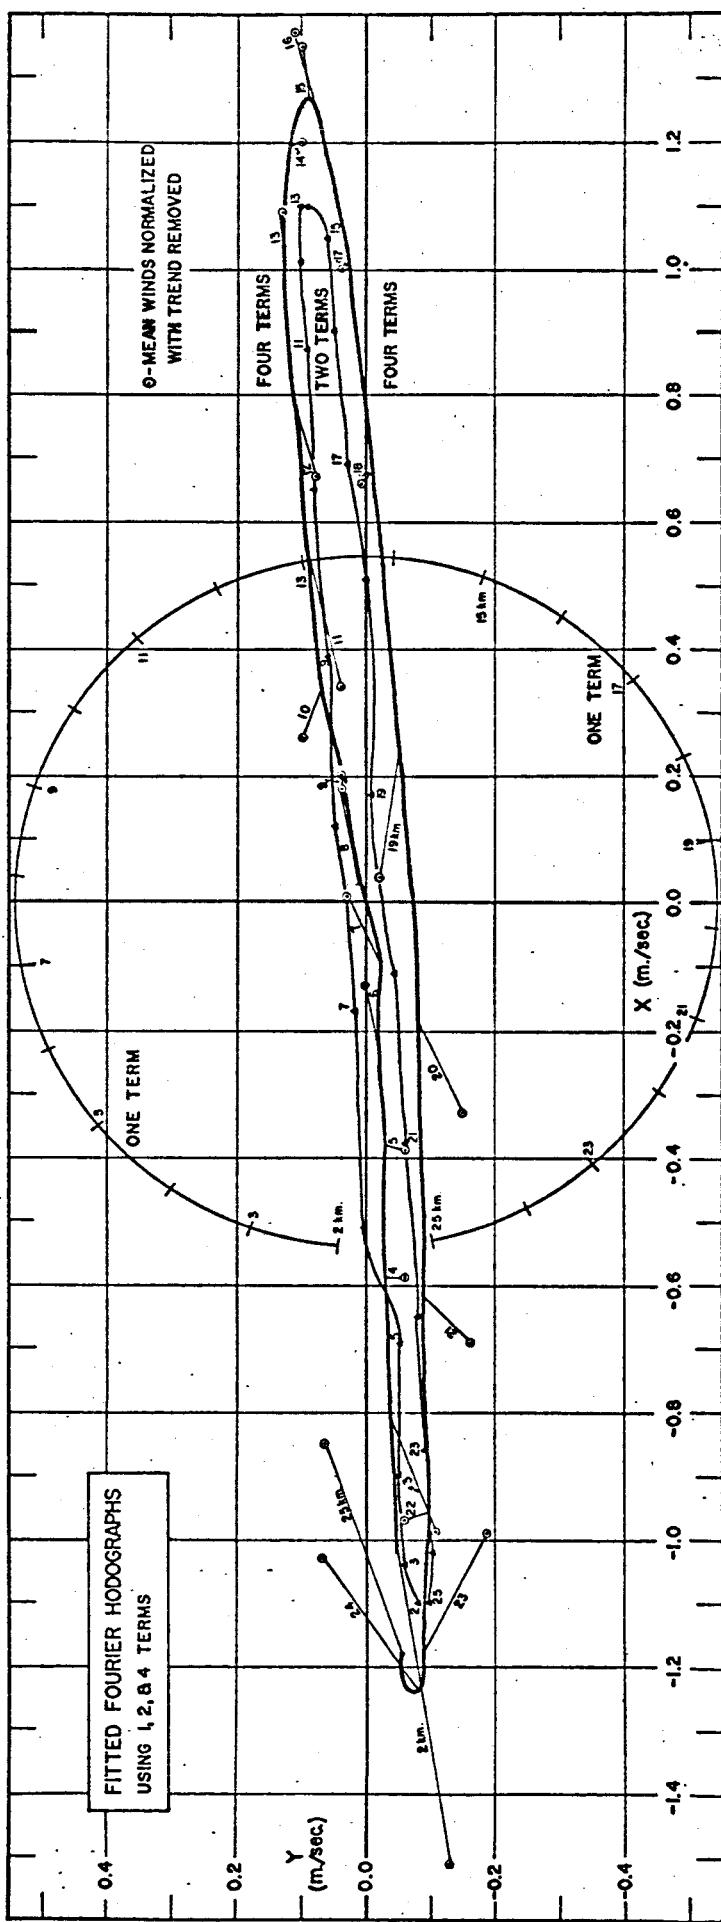

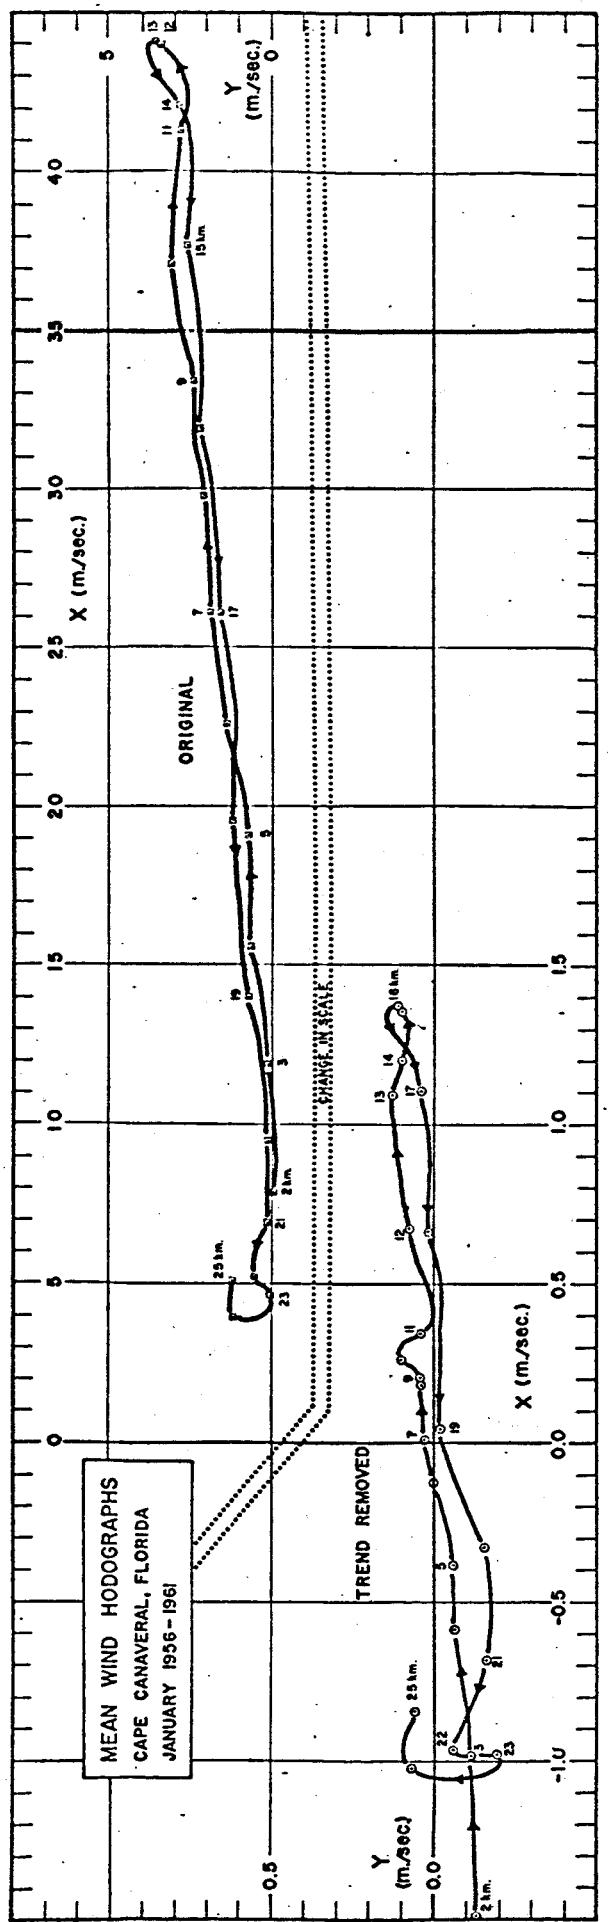

These two sets of data provided a total of 20 "soundings," each sounding being a set of values of  $\{v_h\}$  for successive values of  $h$ . Of these, 12 were monthly means for Cape Canaveral, four were successive wind observations at Montgomery, and four were the corresponding momentum

density observations. For each such "soundings," the lowermost 2 km were ignored, because of possible friction layer effects, as discussed in Section 3, and only the levels from 2 to 25 km, inclusive, were used. In the notation already developed,  $h_0 = 2$  km,  $h_1 = 3$  km, ...,  $h_{2N} = 25$  km. Although the theoretical development uses an odd number,  $N = 2N + 1$ , of values (levels), in actual practice an even number is more convenient; of greatest convenience is a number which is an integral divisor of 250, simplifying trigonometric computations.

Results of the fitting of the augmented Fourier polynomials to these 20 soundings are given in Tables 1 and 2. After the constant and linear terms, the coefficients are presented in decreasing order of the amount of variance "explained" by them. That is, the coefficients  $d_j$  have been ordered as  $d_{(j)}$ , as discussed in Section 4. For example, in the first line of Table 1 (for January mean winds over Cape Canaveral),  $a(1)$  and  $b(1)$  are, respectively,  $a_{23}$  and  $b_{23}$ , so that  $j = 23$  is used in the trigonometric terms that they multiply.

Coefficients are given in Tables 1 and 2 for each wind component separately, as indicated in the formulas at the head of Table 2, which are based on (5.8) and (6.1). The two formulas may be combined into one expression, in complex notation. Thus the mean January wind over Cape Canaveral may be written as

$$\begin{aligned}
 & \text{small } \\
 & \text{ess } \\
 & \sum_{h=1}^s = (2.61 + 0.126 i) - (0.054 - 0.003 i) h \\
 & \quad -(0.575 - 0.014 i) \cos 23\pi h/12 - (0.014 + 0.575 i) \sin 23\pi h/12 \\
 (7.1) \quad & \quad -(0.530 + 0.100 i) \cos \pi h/12 + (0.100 - 0.530 i) \sin \pi h/12 \\
 & \quad +(0.044 + 0.173 i) \cos 22\pi h/12 - (0.173 - 0.044 i) \sin 22\pi h/12 \\
 & \quad +(0.043 - 0.140 i) \cos 2\pi h/12 + (0.140 + 0.043 i) \sin 2\pi h/12 .
 \end{aligned}$$

zeta

The superscript "s" indicates that the values of  $\beta_{h,M}^s$  obtained from (7.1), and from Table 1 generally, are for "standardized" values. They must be multiplied by the standard deviations of the wind components at the appropriate level to give values approximating the observed means.

For example, evaluation of (7.1) for  $h=10$ , i.e. 12 km, gives  $2.41 + 0.226i$ . When each of these values is multiplied by the standard deviation of the corresponding wind component at 12 km over Cape Canaveral in January, 16.0<sub>s</sub> and 11.24 m/sec, respectively, estimated wind speeds are obtained which may be compared with the observed means:

Estimated	$x_{10} = 38.66$	$y_{10} = 3.22$
Observed	44.0 <sub>s</sub>	3.26

In Fig. 2, five hodographs are shown for the mean January winds over Cape Canaveral. In the upper panel, one hodograph depicts the actual means, in meters per second, while a second one shows the effect of dividing the speed at each level by its standard deviation, and expressing the result as a departure from the least-squares plane. The "trend" hodograph is centered at the origin, and is in units much smaller than those of the original values.

The lower panel of Fig. 2 shows three hodographs, computed by Fourier polynomials, not augmented, i.e. as variations about the least-squares plane. The "one-term" hodograph is a circle, representing only the  $j=23$  term, without the preceding constant and linear terms or the final three terms. The "two-term" hodograph represents computation of the  $j=23$  and  $j=1$  terms in (7.1), without the constant and linear terms or the final two terms. The "four term" hodograph presents results of using all terms of (7.1) except the constant and linear.

Shown as dots in the lower panel of Fig. 2 are the same points, for each 1-km level, as in the "trend removed" hodograph of actual winds in the upper panel. The thin lines from these dots to the "four term" curve indicate the extent of the vector difference between the observed mean winds, at each level, and the values computed from (7.1).

etc. The sum of the squares of the lengths of these thin lines is the  $S_{\eta, M}^2$  of (6.3), for  $M=4$ .

For the individual soundings over Montgomery, no estimates of wind variance at each level were readily available. The observed values were assumed to have the same variance, and no adjustments were made. Thus the coefficients in Table 2, when introduced into the appropriate formula, give estimated winds directly in meters per second.

## 8. Discussion

Under each pair of coefficients in Tables 1 and 2 are two additional entries: the value of the index  $j$  for that pair, and the value of  $r^2$ , the relative reduction in variance (4.4) attained by using that term, and all preceding ones, in the augmented Fourier polynomial.

For the Cape Canaveral mean monthly wind profiles, the constant and linear terms alone reduce the variance by 80 % in summer, but hardly at all in November and December. Two additional terms provide  $r^2$  of 85 % or more in all months, indicating that augmented Fourier polynomials of as few as four terms ( $n = 2$ ) may provide descriptions adequate for some purposes. In nine of the months, term 23 provides the greatest reduction in variance, followed by term 1, while the same terms appear in reverse order in the other three months.

For all four Montgomery 6-hourly soundings, term 1 contributes most to the reduction in variance for both wind speed and momentum density. But whereas term 23 is second most important for wind speed, terms 2 (once) and 22 (thrice) have this role for momentum density. Values of  $r^2$  for momentum density are consistently higher than for wind speed alone. Most of this difference arises in the constant and linear terms, for which  $r^2$  is between 75 and 86 % for momentum density, but only from 39 to 44 % for wind speed. This may be a reflection of "Egnell's law," outlined in Section 3, and requires further study.

The extent to which these results depend on the particular height interval chosen also requires additional investigation. The strongest wind speeds in all the soundings are near the middle of the 2-to-26 km interval studied, which may explain the consistent appearance of term 1 as contributing significantly to the relative reduction in variance.

Similarly, the importance of term 23 may indicate excessive level-to-level variability, perhaps actual but also possibly arising from observational errors and computational procedures in the compilation of wind information.

These and other considerations indicate that the most fruitful application of augmented Fourier polynomials to wind profile description may be their use to describe the position hodograph, as obtained directly from a balloon or other indicator, and the subsequent differentiation of the polynomial to provide wind speeds. This may provide considerable improvement over the present method employing successive finite differences, and may give greater detail of the wind profile and of its derivative, the wind shear.

Other topics for further study are statistical tests for the similarity or differences of two wind profiles, leading to criteria for their combination. For example, are January and February wind profiles over Cape Canaveral sufficiently similar that a combined winter profile describes them adequately? Also requiring study are procedures for predicting one profile from another, as in the case of the 6-hourly soundings over Montgomery.

Despite the need for these various extensions of the study, and further elaboration of the technique, the work reported here shows that mathematical description of an entire wind profile, either "means" or "instantaneous," can be attain with acceptable precision by the use of augmented Fourier polynomials.

Appendix A : Estimation of Coefficients

Complex coefficients  $d_j = a_j + i b_j$ , for  $j = 0, 1, \dots, 2N$ , are to be estimated from a set of  $N = 2N + 1$  complex numbers  $\eta_h$  so as to minimize the sum of the squared differences

$$(A-1) \quad s_{\eta;M}^2 = \sum_{h=0}^{2N} s_{\eta;h,M}^2 = \sum_{h=0}^{2N} (\eta_h - \eta_{h,M}) (\eta_h - \eta_{h,M})^*$$

for each index set  $M$  containing  $1 \leq n \leq N$  elements, when the estimators  $\eta_{(h;M)}$  are obtained from

$$(A-2) \quad \eta_{h,M} = \sum_{j \in M} d_j \exp(i \lambda j h), \quad \lambda = 2\pi/\nu.$$

The  $\nu$  numbers  $\{\eta_h\}$  are assumed to represent values or observations at  $\nu$  equal intervals  $h = 0, 1, \dots, 2N$ . These may be intervals of time or space; in the specific applications to be made here they are equal intervals of height, and the numbers  $\{\eta_h\}$  represent wind vectors at successive levels in the atmosphere. These vectors are expressed as departures from a plane of best fit, in the sense of minimizing variance, to the basic data; that is, any linear trend with height has been removed.

For each value of  $h$

$$(A-3) \quad \begin{aligned} s_{\eta;h,M}^2 &= (\eta_h - \eta_{h,M}) (\eta_h^* - \eta_{h,M}^*) \\ &= (\eta_h - \sum_M d_j e^{i \lambda j h}) (\eta_h^* - \sum_M d_j^* e^{-i \lambda j h}) \\ &= \epsilon_h^2 + \left| \sum_M d_j e^{i \lambda j h} \right|^2 - 2 \Re(\eta_h \sum_M d_j^* e^{-i \lambda j h}), \end{aligned}$$

---

\* The asterisk, \*, denotes the complex conjugate.

because  $\eta_h \eta_h^* = |\eta_h|^2 = v_n^2$ , in the notation of Section 1.  
 Since  $\exp[i\lambda h(j-k)] = 1$  when  $j = k$ , the second term becomes

$$(A-4) \quad \begin{aligned} \left| \sum_{j \in H} d_j e^{i\lambda j h} \right|^2 &= \sum_{j \in H} \sum_{k \in H} d_j d_k^* e^{i\lambda h(j-k)} \\ &= \sum_{j \in H} |d_j|^2 + \sum_{j \neq k} d_j d_k^* e^{i\lambda h(j-k)}. \end{aligned}$$

alpha  
beta

Expression of  $\eta_h \exp(-i\lambda j h)$  as  $\alpha_{hj} + i\beta_{hj}$  permits the final term to be written as

$$(A-5) \quad \begin{aligned} \eta_h \sum_{j \in H} d_j^* e^{-i\lambda j h} &= \sum_{j \in H} d_j^* \eta_h e^{-i\lambda j h} \\ &= \sum_{j \in H} (a_j - i b_j) (\alpha_{hj} + i \beta_{hj}) \\ \text{Since } |d_j|^2 &= a_j^2 + b_j^2 \text{ and } \sum \exp[i\lambda h(j-k)] = 0, \end{aligned}$$

the sum of squares (A-1) to be minimized becomes

$$(A-6) \quad \begin{aligned} s_{\eta_{jH}}^2 &= \sum_{h=0}^{2N} s_{\eta_{jh}, H}^2 = \sum_{h=0}^{2N} v_n^2 + 2 \sum_{j \in H} (a_j^2 + b_j^2) \\ &\quad - 2 \sum_{h=0}^{2N} \sum_{j \in H} (a_j \alpha_{hj} + b_j \beta_{hj}). \end{aligned}$$

The usual minimisation procedures give, for each value of  $j$ ,

round  
delta

$$(A-7) \quad \begin{aligned} \frac{\partial s_{\eta_{jH}}^2}{\partial a_j} &= 2 \sum_{h=0}^{2N} a_j - 2 \sum_{h=0}^{2N} \alpha_{hj}, \\ \frac{\partial s_{\eta_{jH}}^2}{\partial b_j} &= 2 \sum_{h=0}^{2N} b_j - 2 \sum_{h=0}^{2N} \beta_{hj}. \end{aligned}$$

Setting these derivatives equal to zero gives

$$(A-8) \quad a_j = \frac{1}{N} \sum_{h=0}^{2N} x_{hj}, \quad b_j = \frac{1}{v} \sum_{h=0}^{2N} \beta_{hj}.$$

Consequently,

$$(A-9) \quad d_j = \frac{1}{v} \sum_{h=0}^{2N} (\alpha_{hj} + i\beta_{hj}) = \frac{1}{v} \sum_{h=0}^{2N} \eta_h \exp(-i\lambda_j h).$$

For computation, the real and imaginary parts are evaluated separately:

$$(A-10) \quad a_j = \frac{1}{v} \sum_{h=0}^{2N} [u_h \cos(\lambda_j h) + v_h \sin(\lambda_j h)],$$

$$b_j = \frac{1}{v} \sum_{h=0}^{2N} [v_h \cos(\lambda_j h) - u_h \sin(\lambda_j h)].$$

In polar co-ordinates,

$$(A-11) \quad a_j = \frac{1}{v} \sum_{h=0}^{2N} w_h \cos(\xi_h - \lambda_j h),$$

$$b_j = \frac{1}{v} \sum_{h=0}^{2N} w_h \sin(\xi_h - \lambda_j h).$$

Use in (A-2) of any set of  $m$  of these values for  $d_j = a_j + i b_j$  will insure that the resulting estimator,  $\eta_{hM}$ , when introduced into (A-1), will minimize the sum of squares  $S_{\eta_{hM}}^2$ . When  $n=1$ , i.e. when the sum (polynomial) has as many terms as the original observations,  $S_{\eta_{hM}}^2 = 0$ . For smaller sets, i.e. for  $m < v$ , the sum of squares  $S_{\eta_{hM}}^2$  will depend on the exact composition of the set  $M$ . Thus  $S_{\eta_{hM}}^2$  can be computed for each of the  $v$  sets  $M$  in which  $n=1$ , i.e., for one term only, and for the  $v(v+1)/2$  sets of two terms each, and so on, to find the combination giving an acceptably small  $S_{\eta_{hM}}^2$  from the smallest set  $M$ .

However, when the coefficients  $\{d_j\}$  are orthogonal, the contribution of each is independent of that of the others, and

$$(A-12) \quad s_{\eta j M}^2 = \sum_{j \in M} s_{\eta j j}^2 .$$

Then,  $s_{\eta j j}^2$  can be computed for each orthogonal  $d_j$  and ranked in descending order to determine the minimum set  $M$  for which  $s_{\eta j M}^2$  is acceptably small. The extent to which the coefficients  $\{d_j\}$ , estimated by (A-9), (A-10), or (A-11), satisfy these requirements is examined in Appendix B.

## Appendix B: Orthogonality

This appendix, investigating the validity of the assumption that the  $\{d_j\}$  are orthogonal, is not quite complete. It will be furnished in about 2 weeks, and will consist of about 4 pages of text, without figures or tables -- quite similar to Appendix A.

## Appendix B: Orthogonality

Orthogonality of the coefficients  $d_j$  in the Fourier polynomials is very desirable for several reasons. When they are orthogonal, i.e. statistically uncorrelated, so will be the numbers  $\{ \hat{\gamma}_{h,m} \}$  estimated by them. Then the contribution of each  $d_j \exp(i\lambda_j h)$  to the estimate  $\hat{\gamma}_{h,m}$  is independent of that of any other term, and the importance of each may be assessed separately. This permits the ready selection of a small set,  $N$ , of  $m$  coefficients for estimating  $\{\hat{\gamma}_{h,m}\}$ , and an exact determination of the extent of the correspondence between each  $\hat{\gamma}_{h,m}$ , as computed, and the quantity  $\gamma_h$  it is intended to approximate.

In addition to orthogonality, normality (Gaussian distribution) is also desirable. If the observations  $\{ \gamma_h \}$  are jointly Gaussian, so will be their departures  $\{ \epsilon_h \}$  from a plane of best fit. In fact, the departures will be approximately Gaussian even if the original observations are not. The estimators,  $d_j$ , will also be Gaussian, or nearly so, because they are weighted sums of quasi-Gaussian variables.

Orthogonality of the  $d_j$  is almost impossible to establish unless the  $\{ \gamma_h \}$  are second-order stationary with a real covariance function. The need for second-order stationarity, that is, that the covariance of  $(\gamma_{h,m}, \gamma_{l,m})$  depend only on the difference  $|h-l|$ , appears in the evaluation of the expression for the variances of the individual  $d_j$ . When the expectations of the  $\{ \gamma_h \}$ , and hence of the  $\{ d_j \}$ , are zero, the variance of each  $d_j$  is given by

$$(P-1) \quad E(d_j d_j^*) = -2 \sum_{h=0}^{N-1} \sum_{l=0}^{N-1} \exp[i\lambda_j(l-h)] E(\epsilon_h \bar{\epsilon}_l).$$

\* The asterisk, \*, denotes the complex conjugate.

This involves the covariance of the observed values, or their departures from the plane, which in turn depends on the correlation ( $r$ ) between the two components:

$$(B-2) \quad E(d_h d_{\ell})^* = E[(u_h u_{\ell} + v_h v_{\ell}) + i(u_{\ell} v_h - u_h v_{\ell})] \\ = [r(u_h, u_{\ell}) + r(v_h, v_{\ell})] + i[r(u_{\ell} v_h) - r(u_h v_{\ell})]$$

Second-order stationarity requires that these correlations depend, for each variable  $u$  or  $v$ , and for any separation  $h - \ell$ , denoted as  $\tau_u$ , only on the separation:

$$(B-3) \quad r(u_h v_{\ell}) = r_u(h - \ell) = z_u(\cdot) = r_u(-\cdot)$$

Certain properties of the separation  $\tau$  are needed:

$$(B-4) \quad \begin{aligned} \tau &= h - \ell, & -2N &\leq \tau \leq +2N, \\ \max(-1, 0) &\leq \ell & \min(2N-1, 2N) \end{aligned}$$

In this notation, (B-2) becomes

$$(B-5) \quad E(d_h d_{\ell})^* = [z_u(\cdot) + z_v(\cdot)] + i[z_{uv}(-\cdot) - z_{uv}(\cdot)] \\ = C(\cdot),$$

where  $C$  may be called a correlation function. If the two components,  $u$  and  $v$ , are uncorrelated,  $C(0) = 2$ , because  $z_u(0) = z_v(0) = 1$ . In terms of this function  $C$ , the expression (B-1) for the variance is

$$(B-6) \quad E(d_j d_{\ell})^* = \omega^{-2} \sum_{-\infty}^{+\infty} C(\cdot) \exp(-j\cdot \beta \cdot) (\cdot - \ell) \\ = \omega^{-2} \sum_{-\infty}^{+\infty} (1 - |\gamma(\cdot)|) \cos(\cdot \beta \cdot) \Re[C(\cdot)].$$

$$= \sigma^{-1} \left[ c(0) + 2 \sum_{j=1}^{2N} (1 - \tau(j)) \cos(\lambda_j \tau) \Re(c(\tau)) \right]$$

because the variance is real-valued. [All summations are over the range of  $\tau$  given by (E-1).]

Similarly, the covariance function for the coefficients is

$$\begin{aligned} E(d_j d_k^*) &= \sigma^{-2} \sum_{n=0}^{2N} \sum_{\tau=0}^{2N} \exp \left[ s(\lambda_j n \tau + \lambda_k n \tau) \right] \\ (E-6) \quad &= \sigma^{-2} \sum_{\tau=0}^{2N} c(\tau) \exp \left( -\frac{\pi^2}{r} \tau^2 \sum_p (a_p + \bar{a}_p) e^{i \lambda_p \tau} \right), \quad p = k-s, \end{aligned}$$

because  $k\ell - jh = s_p - s$ . This must now reduce to 0, since  $a_p + \bar{a}_p$  is orthogonal. To determine whether such is the case, (E-6) may be evaluated term by term, invoking the orthogonality properties of trigonometric series.

$$\text{Since } \sum_{j=0}^N r^j = (1 - r^{N+1}) / (1 - r),$$

$$(E-7) \quad \sum_{j=0}^{2N} \exp(i \lambda_j p) = \begin{cases} \frac{1 - [\exp(i \lambda_p)]^N}{1 - [\exp(i \lambda_p)]} & p \neq 0, \\ 2N + 1 = \lambda_p & p = 0. \end{cases}$$

The last summation in (E-6), over  $\tau$ , is, by definition (E-1), from  $\max(-\tau, 0)$  to  $\min(2N - \tau, 2N)$ , and hence depends on  $\tau$ . It may be denoted as  $\gamma(\tau)$ :

$$(E-8) \quad \gamma(\tau) = \sum_{\ell} \exp(i \lambda_{\ell} \tau) = \begin{cases} \tau = 2N + 1 & \begin{cases} \tau = 0, \\ 0 \leq \ell \leq 2N; \end{cases} \\ \frac{1 - \exp(-i \lambda_p \tau)}{1 - \exp(i \lambda_p)} & \begin{cases} \tau > 0, \\ 0 \leq \ell \leq 2N - \tau; \end{cases} \\ -\frac{1 - \exp(-i \lambda_p \tau)}{1 - \exp(i \lambda_p)} & \begin{cases} \tau < 0, \\ -\tau \leq \ell \leq 2N. \end{cases} \end{cases}$$

Thus  $\gamma(-\tau) = -\gamma(\tau)$  when  $\tau \neq 0$ . In the expression for  $\gamma(\tau)$  when  $\tau > 0$ , multiplication of numerator and denominator by  $1 - \exp(-i \lambda_p)$  gives

$$\begin{aligned}
 Y(\tau) &= \frac{1 - e^{-i\lambda_p} - e^{i\lambda_p\tau} + e^{-i\lambda_p(\tau+1)}}{2 - (e^{i\lambda_p} + e^{-i\lambda_p})} \quad \tau > 0 \\
 &= \frac{1 + \cos\lambda_p + i \sin\lambda_p - \cos\lambda_p\tau - i \sin\lambda_p\tau}{2 + \cos\lambda_p(\tau+1) - i \sin\lambda_p(\tau+1)} \\
 (P-8) \quad &= \frac{2 - 2 \cos\lambda_p}{2 - (1 - \cos\lambda_p)} \\
 &= \frac{1 + \cos\lambda_p(2N-\tau) - \cos\lambda_p(\tau-1) - \cos\lambda_p}{2(1 - \cos\lambda_p)} \\
 &\quad - i \frac{\sin\lambda_p(2N-\tau) - \sin\lambda_p(\tau-1) - \sin\lambda_p}{2(1 - \cos\lambda_p)}
 \end{aligned}$$

This is small when  $\tau$  is small.

Next, the correlation function  $C(\tau)$  must be examined. It is real if and only if it is even, i.e. if  $r_{xy}(-\tau) = r_{xy}(\tau)$ . In this case, (P-5) becomes

$$\begin{aligned}
 E(d_j d_k^*) &= \frac{1}{N} \left\{ C(0) + \sum_{\tau=1}^{2N} C(\tau) e^{-i\lambda\tau} [Y(\tau)/N] \right. \\
 &\quad \left. + \sum_{\tau=1}^{2N} C(-\tau) e^{i\lambda\tau} [Y(\tau)/N] \right\} \\
 (I-10) \quad &= \frac{1}{N} \left\{ C(0) + \sum_{\tau=1}^{2N} C(\tau) [Y(\tau)/N] [e^{i\lambda\tau} - e^{-i\lambda\tau}] \right\} \\
 &= \frac{1}{N} \left\{ C(0) + \sum_{\tau=1}^{2N} C(\tau) [Y(\tau)/N] [2i \sin\lambda\tau] \right\}.
 \end{aligned}$$

Term by term examination of this result shows that, when

$$\begin{aligned}
 C(0)/N &= 1/12 \approx 0.08 \quad \text{when} \quad N = 2n+1 = 2L, \\
 C(\tau)/N &\rightarrow 0 \quad \text{as} \quad \tau \rightarrow \infty, \\
 C(\tau)/N &\rightarrow 0 \quad \text{as} \quad \tau \rightarrow 0, \\
 \sin(\lambda\tau)/N &\rightarrow 0 \quad \text{as} \quad \tau \rightarrow 0.
 \end{aligned}$$

Thus  $E(d_j d_k^*)$ , apparently is always small, although that it is identically zero for all  $\tau$ , as is required for complete orthogonality, has not

been proved. Actually,  $E(d_{ij}d_{ik}) \rightarrow 0$  as  $2N+1 \rightarrow \infty$ , i.e. as more and more levels are used and the discrete model approaches a continuous one. Thus the question of orthogonality may be analogous to the general problem of the extent to which large sample theory can be used for small samples, or to which properties of a continuous function can be applied to a discrete one.

For the present purpose, the assumption of orthogonality seems reasonable. Very slight interdependence of the  $\{d_{ij}\}$  will not affect materially the general results. This assumption permits the determination of the variance contribution of each term separately, and the addition of such separate contributions to estimate the total variance from a linear combination of terms.
